Prerequisite-Aware Study Scheduling

Exact and Approximation Algorithms for the DAG-Constrained Knapsack Problem

Abstract

Modern education systems present students with a complex resource allocation problem: selecting a subset of chapters to maximize academic reward under a strict time budget. When knowledge is structured as a Directed Acyclic Graph (DAG), this selection task becomes the Precedence-Constrained Knapsack Problem (PCKP), which is known to be NP-Hard. This research investigates the failure modes of classical Dynamic Programming (DP) in structured environments, specifically identifying the *State Eviction Bug* and *Shared Ancestor Double-Counting*. We implemented a hybrid algorithmic pipeline consisting of SAT-Gated Greedy heuristics, an exact Bitmask DP solver for theoretical validation, and a Fully Polynomial-Time Approximation Scheme (FPTAS). We provide a rigorous mathematical proof showing that our FPTAS guarantees a solution within $(1 - \epsilon)$ of the global optimum. Experimental results on a 5,000-node synthetic syllabus demonstrate that our approach scales linearly, bypassing the exponential memory wall of $O(2^N W)$ and delivering near-optimal plans in milliseconds.

Keywords: PCKP, Directed Acyclic Graph, SAT-Gating, Bitmasking, FPTAS, Approximation Algorithms, Curriculum Optimization.

1 Introduction

The fundamental challenge in end-semester exam preparation is not merely the act of learning, but the strategic *selection* of what to learn under a fixed temporal constraint W. A student operating in this environment acts as a biological optimizer, attempting to maximize a cumulative reward function (marks) while navigating a web of prerequisites.

1.1 The Cognitive Burden of Curriculum Planning

In a standard 0/1 Knapsack scenario, items are independent entities. However, a real-world syllabus is a hierarchy. One cannot master *Matrix Calculus* without first satisfying the prerequisite of *Linear Algebra*. Mathematically, selecting an advanced node v forces the student to "pay" for the entire ancestor closure of v.

Research in cognitive load theory suggests that the human working memory can only manage roughly 7 ± 2 units of information simultaneously. When faced with a syllabus of $N = 100$ interconnected topics, the search space for the optimal subset grows to $2^{100} \approx 10^{30}$ combinations. This exceeds the capacity of human intuition, forcing students to rely on local greedy heuristics (e.g., picking chapters with the most marks), which we prove in Section 3 are mathematically guaranteed to fail in the presence of deep dependency chains.

1.2 Problem Scope: Beyond the "To-Do" List

We distinguish Study Scheduling from a simple To-Do list. In a To-Do list, the cost of a task is its individual duration. In a syllabus DAG, the **Effective Cost** of a chapter is the sum of the time costs of all its mandatory prerequisites not yet completed. This structural dependency necessitates a transition from memoryless solvers to state-aware algorithms that preserve selection history.

2 Mathematical Preliminaries and Formulation

To develop a provably correct scheduler, we must first formalize the syllabus structure and the optimization goals using the language of discrete mathematics.

2.1 Graph Theoretic Foundations

We model the curriculum as a Directed Acyclic Graph (DAG), denoted by $G = (V, E)$.

- **Vertices (V):** The set $V = \{v_1, v_2, \ldots, v_n\}$ represents the atomic units of the syllabus (e.g., subtopics or chapters). Each node v_i is associated with two non-negative real numbers: a study time $t_i \in \mathbb{R}^+$ and a mark reward $m_i \in \mathbb{R}^+$.
- **Directed Edges (E):** The set $E \subseteq V \times V$ represents the mandatory prerequisite rules. An edge $(u, v) \in E$ indicates that chapter u must be fully completed before chapter v can be initiated.

Acyclicity: The graph G must contain no directed cycles. If a cycle $v_1 \to v_2 \to \cdots \to v_k \to v_1$ existed, the syllabus would be logically impossible to complete, as each node in the cycle would wait for the next in an infinite loop. We guarantee acyclicity in our datasets through a level-based monotonic ranking system (see Section 7.1).

2.2 The Prerequisite Partial Order ($\preceq$)

The edges in E induce a **Partial Order** relationship on V. We say $u \preceq v$ if there exists a directed path from u to v. This relationship satisfies the following properties:

1. **Reflexivity:** $v \preceq v$ (a chapter is a prerequisite for itself).
2. **Antisymmetry:** $u \preceq v$ and $v \preceq u \implies u = v$ (prevents cycles).
3. **Transitivity:** $u \preceq v$ and $v \preceq w \implies u \preceq w$ (indirect prerequisites).

2.3 The Closure Property and Feasibility

The most critical constraint in our study is the **Closure Property**. A valid study plan $S \subseteq V$ is not just any collection of items; it must be a **Downward-Closed Set**.

Downward-Closed Set / Ideal: A subset $S \subseteq V$ is downward-closed if, for every chapter v included in S, all of its ancestors are also included:

$$\forall v \in S, \quad \{u \in V : u \preceq v\} \subseteq S \tag{1}$$

The **Closure Operation** $\mathrm{Cl}(S)$ represents the "Baggage Rule": if a student picks a set of chapters S, the computer must "fill in the gaps" by adding every node u such that $u \preceq v$ for any $v \in S$. The difficulty of our optimization arises because the cost of a chapter is not constant; it depends on how many of its prerequisites are already paid for in a previous step.

2.4 PCKP Optimization Model

We formally define the Precedence-Constrained Knapsack Problem (PCKP) as follows. Let x_i be a binary decision variable where $x_i = 1$ if chapter i is selected, and $x_i = 0$ otherwise.

$$\text{Maximize: } Z = \sum_{i=1}^{n} m_i x_i \tag{2}$$

Subject to:

$$\sum_{i=1}^{n} t_i x_i \leq W \qquad \text{(Resource Constraint)} \tag{3}$$

$$x_i \leq x_j \quad \forall (j,i) \in E \qquad \text{(Precedence Constraint)} \tag{4}$$

$$x_i \in \{0,1\} \quad \forall i \in V \qquad \text{(Integrality Constraint)} \tag{5}$$

The precedence constraint (Eq. 4) is the mathematical engine of our system. It ensures that if prerequisite j is not chosen ($x_j = 0$), then the dependent i must also be excluded ($x_i = 0$). This transforms the search from a simple selection of items into a search for the **Maximum Weight Sub-graph Closure**.

3 Computational Complexity Analysis

The Precedence-Constrained Knapsack Problem is not merely a variant of the standard knapsack; it is a significantly more complex optimization challenge. In this section, we analyze the theoretical boundaries of the problem.

3.1 Hardness Proof: Reduction from 0/1 Knapsack

To establish the complexity class of PCKP, we employ a polynomial-time reduction from the classical 0/1 Knapsack problem.

The Precedence-Constrained Knapsack Problem (PCKP) is NP-Hard.

Proof. Consider an arbitrary instance of the 0/1 Knapsack problem consisting of n items, each with value v_i, weight w_i, and total capacity W. We can transform this into a PCKP instance in $O(n)$ time by:

1. Mapping each item i to a vertex v_i with $m_i = v_i$ and $t_i = w_i$.
2. Constructing an empty edge set $E = \emptyset$.

In this constructed instance, the prerequisite constraint is vacuously satisfied for any subset. Thus, the PCKP optimization reduces exactly to the 0/1 Knapsack problem. Since the 0/1 Knapsack is known to be NP-Hard, and it is a special case of PCKP, the general PCKP must be at least as hard. Consequently, PCKP is NP-Hard. □

3.2 Search Space Analysis: The State Explosion

While the DAG structure prunes many invalid combinations (e.g., taking an advanced topic without basics), the search space remains exponential. For a graph with width k, the number of valid closed sets can still grow at a rate of 2^k. In a realistic 5,000-node syllabus, the number of independent subjects (antichains) ensures that a brute-force search is physically impossible on modern hardware.

4 The Failure of Classical Logic

In this section, we identify the specific reasons why standard Dynamic Programming (DP) cannot be applied to study scheduling.

4.1 The Bellman Equation and the Independence Assumption

The classical Bellman recurrence for the Knapsack problem is:

$$dp[w] = \max(dp[w], \quad dp[w - t_i] + m_i) \tag{6}$$

This math relies on the **Independence Assumption**: the utility of chapter i is constant and independent of the set already in the bag. In a syllabus, this is false. The "utility" of a prerequisite node is its own marks *plus* the potential marks of all its reachable descendants.

4.2 The State Eviction Bug: A Trace Analysis

Standard DP suffers from a "Blindness" we call **State Eviction**. Because it only stores the maximum marks at each weight slot, it deletes paths that look "weak" but are actually "mandatory."

Table 1: Trace of State Eviction (Budget $W = 5$)

Step	**Node Processed**	**Slot** $dp[2]$	**Outcome**
1	Start	0	Box Empty
2	Algebra ($t = 2, m = 10$)	10	Algebra Saved
3	Biology ($t = 2, m = 40$)	40	Algebra Evicted!
4	Deep Learning (*needs* Algebra)		Locked Permanently

Analysis: At weight 2, the computer performs $max(10, 40)$. Since 40 is larger, the 10-mark Algebra path is erased. When the algorithm reaches the 100-mark Deep Learning node, it checks the 2-hour slot for the Algebra key. It finds only Biology. The computer concludes the prerequisite is missing and skips the global optimum. Standard logic is too "locally efficient," causing it to throw away the keys to the future.

5 Exact Solution via Bitmasking (Digital History)

To resolve the state memory crisis identified in Section 3, we must abandon the scalar DP table. We propose an expanded state representation that preserves the **Topological Context** of every study plan. We call this the "Digital History" approach.

5.1 State Expansion: From Scalar to Set-State Memory

In a classical knapsack, the state is defined solely by the remaining budget w. To ensure structural integrity in a DAG, we expand the state to include a **Binary State Vector** of the bag's contents.

Instead of a single integer $dp[w]$, we store a mapping:

$$DP[w] = \{(mask_j, marks_j) : S_j \text{ is a valid closure with weight } w\} \tag{7}$$

where $mask_j$ is an integer representation of the set S_j. By storing multiple valid paths for a single weight slot, we prevent the "Biology path" from overwriting the "Math path." Both co-exist as separate entries in the table, ensuring the mandatory keys are never lost.

5.2 The Bitmask Invariant: The Binary Checklist

We assign each chapter $v_i \in V$ a unique index $i \in \{0, \ldots, n-1\}$. A study plan S is then represented as a bitmask:

$$mask = \sum_{i \in S} 2^i \tag{8}$$

Each bit acts as a boolean flag: '1' if the chapter is studied, '0' if not. This transforms the syllabus into a high-speed **Binary Checklist**.

5.3 The SAT-Gate Logic: Prerequisite Synchronization

To enforce DAG rules efficiently, we pre-calculate a **Prerequisite Mask** (P_i) for every node i. This mask encodes the "Keys" required to unlock the node.

[Bitwise SAT-Gate] The transition to add chapter v_i to a state with $mask$ is valid if and only if the following bitwise invariant is true:

$$(mask \text{ AND } P_i) = P_i \tag{9}$$

Bit-Level Execution If chapter v_3 requires chapters $\{v_0, v_1\}$, then $P_3 = 0b0011$.

- **Case A:** $mask = 0b0001$ (Only v_0 present).
  Check: $(0001 \ \& \ 0011) = 0001 \neq 0011$. Gate Locked.
- **Case B:** $mask = 0b0011$ (Both v_0, v_1 present).
  Check: $(0011 \ \& \ 0011) = 0011$. Gate Open.

5.4 The Idempotent Union Update

Once the gate opens, the new state is generated using the **Bitwise OR** (|) operator:

$$mask_{new} = mask_{old} \mid (1 \ll i) \tag{10}$$

Bitwise OR is mathematically **Idempotent** ($1 \vee 1 = 1$). If a node is reachable through two different paths (e.g., in a diamond), the OR operator ensures the bit is set exactly once. This naturally prevents the double-counting of time and marks for shared ancestors, providing a robust solution to the "Diamond Problem" (Section 3.2).

5.5 Computational Ceiling: The Exponential Barrier

While bitmasking is mathematically perfect (an "Oracle"), its complexity is $O(2^n \cdot W)$. Every additional chapter **doubles** the potential state space. Empirically, we observed that for $n = 25$, the map exceeds 12GB of RAM, hitting the "Heap Allocation Wall." This scientific limit necessitates the approximation strategies developed in Section 6.

6 Rigorous Resolution of Path Convergence

A critical requirement of our work is ensuring that shared ancestors do not lead to over-estimation of resource consumption. This structural challenge, often found in "Diamond" or "Cross-Root" topologies, represents a convergence of prerequisite paths.

6.1 The Intersection Problem

In a diamond structure $\{v_{root} \to v_A, v_{root} \to v_B, \{v_A, v_B\} \to v_Z\}$, a naive recursive solver calculates the cost of node v_Z as the sum of its parents' closures. This leads to the *Double-Counting Bias*:

$$\text{Cost}_{naive}(v_Z) = \mu(\text{Cl}(v_A)) + \mu(\text{Cl}(v_B)) + t_{v_Z} \tag{11}$$

where μ represents the measure of time. Since $\text{Cl}(v_A) \cap \text{Cl}(v_B) = \{v_{root}\}$, the time t_{root} is added twice.

6.2 Proof of Bitwise Correctness for Shared Ancestors

[Union-Cost Invariant] The Bitwise OR update rule ensures that the time cost of any shared ancestor is accounted for exactly once in the total weight calculation.

Proof. Let $mask_A$ and $mask_B$ be the binary representations of the closures of nodes v_A and v_B.

1. Let i be the bit-index of the shared ancestor v_{root}. By definition, the i-th bit of both $mask_A$ and $mask_B$ is 1.
2. The algorithm performs the merge: $mask_{merged} = mask_A \mid mask_B$.
3. According to the laws of Boolean Algebra, the i-th bit of the result is $1 \vee 1 = 1$.

Since the total time is calculated by iterating over the set bits of the resulting mask, t_{root} is added to the sum only once. Mathematically, our algorithm calculates the **Measure of the Union** rather than the sum of the measures:

$$T(S_A \cup S_B) = \sum_{i \in S_A \cup S_B} t_i \neq \sum_{i \in S_A} t_i + \sum_{i \in S_B} t_i \tag{12}$$

This property guarantees that the "Junction" node v_Z is only added to the bag if the combined time of the union of all ancestors plus t_{v_Z} fits within W. □

7 Scalable Scaling: FPTAS Implementation

Having established the exact ground truth for small N, we now address the **Scaling Problem**. When $N = 5000$, we must bypass the 2^N barrier. We implement a **Fully Polynomial-Time Approximation Scheme (FPTAS)** by moving from indexing by Weight (Time) to indexing by Scaled Marks.

7.1 The Value-Axis Discretization Insight

A standard DP table for Knapsack has a size of $O(N \cdot W)$. If the time units are high-resolution (e.g., minutes instead of hours), W becomes massive, and the table crashes. FPTAS solves this by **Discretizing the Value Space**.

7.1.1 Why we do not scale the Weight axis?

Scaling weights (time) is *structurally dangerous*. If we round down a chapter's time cost from 4.9 hours to 4 hours, our algorithm might generate a study plan that it **thinks** takes 10 hours, but actually takes 11. This creates an Infeasible Solution that violates the hard budget W.

In contrast, scaling Marks (Value) is **Safe**. If we round down 10.5 marks to 10 units, we simply lose a tiny amount of profit tracking. The study plan remains **Strictly Feasible**.

7.2 Formal Derivation of the Scaling Factor (K)

The goal of FPTAS is to limit the total rounding tax paid across all n items. We define a scaling factor K to reduce the mark values m_i into a smaller integer space m'_i:

$$m'_i = \left\lfloor \frac{m_i}{K} \right\rfloor \tag{13}$$

The total error introduced by this floor function for any set S is $\sum(m_i - K \cdot m'_i)$. Since each item's error is $< K$, the total error for n items is $\leq n \cdot K$. To satisfy our $(1 - \epsilon)$ accuracy guarantee, we set:

$$n \cdot K = \epsilon \cdot M_{max} \implies K = \frac{\epsilon \cdot M_{max}}{n} \tag{14}$$

where M_{max} is the largest single mark value in the syllabus. This choice of K ensures the total error is bounded by a fraction of the optimum, transforming the exponential search into a polynomial-width table of size $O(N^2/\epsilon)$.

7.3 The FPTAS Algorithm: Value-Indexed Dual DP

The FPTAS implementation requires a **Dual DP** approach. Instead of the standard table that asks - **What is the max marks for this weight?**, we use a table that asks - **What is the minimum weight for this mark?**.

Let $dp_{dual}[s]$ store the minimum time required to achieve a total scaled marks of exactly s. The table is initialized with $dp_{dual}[0] = 0$ and all other entries set to ∞. We then iterate through each chapter v in topological order, updating the table with the SAT-Gated transition:

$$dp_{dual}[s] = \min(dp_{dual}[s], dp_{dual}[s - m'_v] + t_v) \tag{15}$$

The final solution is the largest s such that $dp_{dual}[s] \leq W$. This process transforms the complexity from $O(2^N W)$ to $O(N^3/\epsilon)$.

7.4 Mathematical Proof of the $(1-\epsilon)$ Approximation Bound

We now provide a proof that the solution found by our FPTAS solver, Z_{fptas}, is bounded by $(1-\epsilon)$ of the true global optimum, Z_{opt}.

Let S^* be the optimal set of chapters and S_f be the set of chapters selected by the FPTAS. Then:

$$\sum_{i \in S_f} m_i \geq (1-\epsilon) \sum_{i \in S^*} m_i \tag{16}$$

Proof. The proof proceeds by bounding the cumulative rounding loss.

1. **Rounding Inequality:** From the property of the floor function, we have $x-1 < \lfloor x \rfloor \leq x$. Therefore, for each scaled mark $m'_i = \lfloor m_i/K \rfloor$:

$$\frac{m_i}{K} - 1 < m'_i \leq \frac{m_i}{K} \tag{17}$$

   Multiplying by K, we get the bound on the original mark:

$$m_i - K < K \cdot m'_i \leq m_i \tag{18}$$

2. **Scaled Optimality:** Since our Dual DP is exact on the scaled values, the sum of scaled marks in our solution S_f must be at least as large as the sum of scaled marks in the true optimal set S^*:

$$\sum_{i \in S_f} m'_i \geq \sum_{i \in S^*} m'_i \tag{19}$$

3. **Combining the Bounds:** We can now bound the actual value of our FPTAS solution (Z_{fptas}) relative to the optimum (Z_{opt}):

$$\begin{aligned} Z_{fptas} = \sum_{i \in S_f} m_i &\geq \sum_{i \in S_f} K \cdot m'_i && \text{(From Eq. 17)} && (20) \\ &\geq \sum_{i \in S^*} K \cdot m'_i && \text{(From Eq. 18)} && (21) \\ &> \sum_{i \in S^*} (m_i - K) && \text{(From Eq. 17)} && (22) \\ &= \sum_{i \in S^*} m_i - |S^*| \cdot K && \text{(Distributive law)} && (23) \end{aligned}$$

4. **Final Substitution:** Since the optimal set has at most n chapters ($|S^*| \leq n$) and we defined $K = \frac{\epsilon \cdot M_{max}}{n}$, we have:

$$Z_{fptas} > Z_{opt} - n \cdot \left(\frac{\epsilon \cdot M_{max}}{n} \right) = Z_{opt} - \epsilon \cdot M_{max} \tag{24}$$

   In any non-trivial syllabus, the global optimum Z_{opt} is at least as large as the single most valuable node M_{max}. Therefore, $\epsilon \cdot M_{max} \leq \epsilon \cdot Z_{opt}$. Substituting this:

$$Z_{fptas} \geq Z_{opt} - \epsilon \cdot Z_{opt} = (1-\epsilon) \cdot Z_{opt} \tag{25}$$

   The proof is complete.

□

8 Synthetic Data Engine

To guarantee robustness, we engineered a specific set of Pathological Scenarios instead of relying on uniform random graphs. A uniform random distribution fails to create dense bottlenecks. We developed a **Level-Based Fan-In engine** guaranteeing a 70% multi-parent density.

8.1 Hierarchical Level Assignment and Acyclicity

To ensure our datasets mirror the structure of real curricula, we implement a **Monotonic Level Assignment** strategy. We divide the n nodes into five discrete levels (0 = Foundational, 4 = Capstone). An edge (u, v) is only instantiated if $L(u) < L(v)$.

The level-based constraint guarantees that the generated graph G is a Directed Acyclic Graph (DAG).

Proof. Suppose a cycle exists: $v_1 \to v_2 \to \cdots \to v_k \to v_1$. By the edge rule, we have $L(v_1) < L(v_2) < \cdots < L(v_k) < L(v_1)$. This implies $L(v_1) < L(v_1)$, which is a logical contradiction. Thus, no cycle can exist. □

8.2 Goldilocks Budgeting for Maximum Hardness

The difficulty of a Knapsack instance is defined by the **Capacity Ratio** $\gamma = W/\sum t_i$.

- If $\gamma \to 0$, the problem is trivial (nothing fits).
- If $\gamma \to 1$, the problem is trivial (everything fits).

Research into the *Phase Transition* of NP-Hard problems suggests that the maximum computational struggle occurs at $\gamma \approx 0.5$. Consequently, we algorithmically scale the budget W to exactly 50% of the total cumulative study time for every generated dataset.

9 Experimental Benchmarking

We executed our hybrid pipeline on synthetic datasets ranging from **N=10** to **N=5000**.

9.1 Accuracy vs. Heuristic (The Greedy Gap)

For small-scale validation ($N = 10$), we observed a significant **Optimality Gap**. The SAT-Gated Greedy algorithm scored 61 marks, while the Bitmask DP identified the true optimum of 208 marks.

$$\text{Competitive Ratio } (Greedy) = \frac{Z_{greedy}}{Z_{opt}} \approx 0.29 \tag{26}$$

This confirms that local efficiency ratios are poor proxies for global utility in high-convergence DAGs.

9.2 Empirical Verification of the Memory Wall

As predicted by the $O(2^N W)$ complexity, the Bitmask solver encountered a **Physical Resource Ceiling**.

Table 2: Memory Consumption and Outcome Analysis

N	States (2^N)	RAM Usage	Outcome
15	32,768	< 10 MB	Instant
22	4,194,304	~ 2.1 GB	Feasible
26	67,108,864	12.4 GB	Heap Failure
30	1,073,741,824	~ 850 GB	Impossible

9.3 FPTAS Scalability and Weight-Independence

In the $N = 5000$ scenario, the Bitmask DP was mathematically impossible. However, the FPTAS solver (with $\epsilon = 0.01$) executed in 450ms.

- **Observation:** The FPTAS runtime remained stable even when the time budget W was increased by a factor of 100.
- **Scientific Conclusion:** This confirms the **Weight-Independent** nature of the $O(n^3/\epsilon)$ complexity. By discretizing the value-space, we have successfully decoupled the solver's performance from the magnitude of the study budget.

10 Pathological Case Study: Rigorous Stress-Testing

To guarantee the structural integrity of our SAT-Gating logic, we evaluated the hybrid pipeline against 14 specifically engineered Pathological Syllabi. These structures are designed to break naive DP logic and verify the robustness of our mathematical invariants.

10.1 Success Metrics

Both the Bitmask DP and the FPTAS achieved a **100% Pass Rate** for feasibility. Every study plan generated was a valid downward-closed set. In the Competing Chains test, FPTAS consistently outscored Greedy by an average of 42%, confirming that value-axis scaling preserves the Global Vision of the optimizer.

11 Deep Discussion: The Science of Pruning

Our work revealed a counter-intuitive phenomenon: increasing the density of the DAG (more prerequisites) often *speeds up* the Bitmask solver.

11.1 The Pruning Paradox

In a standard Knapsack, every item is independent, meaning every 2^N combination is a potential winner. In our PCKP model:

- Each prerequisite edge (u, v) acts as a **Logic Filter**.
- It effectively forbids any bitmask where Bit v is 1 but Bit u is 0.

Mathematically, the DAG constraints act as a **Search Space Pruner**. In our high-convergence dataset (70% density), the number of reachable states in the DP table was 60% smaller than in a flat dataset of the same size. This proves that structural complexity is a computational blessing for state-aware algorithms like the SAT-Gated DP.

11.2 Limitations of the Current Pipeline

We identify two primary limitations. First, the **Memory Ceiling** of $N \approx 25$ for exact solutions remains a hardware invariant. Second, the model is **Static**. It assumes that time costs (t_i) are deterministic, whereas real-world study time is often a stochastic variable influenced by student fatigue.

12 Strategic Vision and Future Scope

We envision this project as the foundation for a **Principled Education Service**.

12.1 Multi-Objective Fatigue Modeling

A real student is constrained by more than just time; they are limited by **Cognitive Energy**. We propose extending the PCKP to a **Multi-Dimensional Knapsack**:

$$\text{Maximize} \sum m_i x_i \quad \text{s.t.} \quad \sum t_i x_i \leq W_{time} \quad \text{and} \quad \sum e_i x_i \leq W_{energy} \tag{27}$$

This would prevent **Burnout Plans** where the algorithm picks too many difficult chapters in a single window.

12.2 Adaptive Real-Time Re-Optimization

Since we use Bitmasking, our system can support **Hot-Starts**. If a student completes Chapter A earlier than expected, we do not re-run the entire code. We simply set the corresponding bit in the current mask and run the DP from that state, allowing for a live, adaptive roadmap.

13 Conclusion

This project has successfully bypassed the exponential wall of the Precedence-Constrained Knapsack Problem. By identifying the **State Eviction Bug** in standard logic and developing a **SAT-Gated Hybrid Pipeline**, we have built a tool that is both mathematically exact for small-scale verification and practically scalable for university curricula of 5,000 topics.

Our implementation of the FPTAS provides a provable $(1 - \epsilon)$ guarantee, transforming curriculum planning from an intuitive guess into a principled optimization problem. This work bridges the gap between theoretical combinatorial limits and the practical needs of modern education.

"The goal of an algorithm is not just to find an answer, but to find a path that respects the laws of logic."
